

AN772: Using the Ember Application Bootloader

NOTE: As of the end of 2017, the Ember Application Bootloader was no longer supported for any EFR32 products, only for the EM35x. For all EFR32 products, configure an application bootloader from the Silicon Labs Gecko Bootloader, as described in *UG266: Silicon Labs Gecko Bootloader User Guide*.

This document describes some of the specific types of legacy Ember Application Bootloaders released by Silicon Labs. For general information about bootloaders and how an application bootloader compares with a standalone bootloader, see *UG103.6: Application Development Fundamentals: Bootloading*.

KEY POINTS

- Describes the principles of the application bootloader model compared to the standalone bootloader model.
- Compares and contrasts the available Ember application bootloader variants.
- Lists supported drivers and model numbers for external storage options.

1. Application Bootloading

1.1 Introduction

A bootloader is a program stored in reserved flash memory that can initialize a device, update firmware images, and possibly perform some integrity checks. Silicon Labs networking devices use bootloaders that perform firmware updates in two different modes: standalone (also called standalone bootloaders) and application (also called application bootloaders). A standalone bootloader is a program that uses an external communication interface, such as UART or SPI, to get a firmware update image. NCPs (Network Coprocessors) only support standalone bootloaders. An application bootloader performs a firmware image update by reprogramming the flash with an update image stored in internal or external memory. Application bootloaders can only be used on SoC (System-on-Chip) devices. In March of 2017, Silicon Labs introduced the Gecko Bootloader, a code library configurable through Simplicity Studio's IDE to generate bootloaders that can be used with a variety of Silicon Labs protocol stacks. The SoC model dictates which bootloader must be used. Legacy Ember application bootloaders must be used with all EM3x SoCs. The Gecko Bootloader must be used with all EFR32 SoCs.

An application bootloader begins the firmware update process after the running application has completely downloaded the update image file to a download space. Typically this download space is an external memory device like a dataflash or EEPROM, but, on SoC devices with larger memory capacity, the download space can be a portion of the SoC's internal flash memory. Legacy Ember application bootloader update images must be in the EBL format and stored starting at the logical beginning of the download space. Ember application bootloaders do not support bootloading from multiple images stored in the download space, although it is possible for the application to store as many images as will fit. Note, however, that the Gecko Bootloader can be configured to access multiple images from the download space.

Since acquiring the image is the responsibility of the application, application bootloaders in general are simpler and more flexible than standalone bootloaders. The application is free to upload the new image to the download space any way it wants. The image could come over-the-air from multiple hops away, over a physical connection like the serial port or USB, or anything else the application developer can think of. The application is also free to take as much time as necessary to upload the new image in the background and only program it once ready. The stored image could even be in an encrypted form if the secure application bootloader is used.

Since the new image is stored externally, the current application isn't overwritten until the new image has been successfully saved and verified. If something goes wrong during the update process, the bootloader will automatically try to bootload the image again when restarted. In the unlikely event that both the application image and the image in the download space become corrupted, a legacy Ember application bootloaders can enter a failsafe recovery mode.

The main downside of an application bootloader is that some storage space must be allocated for the download space. In the case of a local storage bootloader, this uses up some quantity of flash that could otherwise be used for the application. In external application bootloader configurations, an external data storage part must be added to the design, which increases the cost.

All application bootloaders are very closely related to each other, but they are generally organized along two dimensions: external versus local storage, and unencrypted versus secure (encrypted).

1.2 Types of Application Bootloaders

The original Ember application bootloader developed by Silicon Labs was an unencrypted external storage bootloader. It expected the download space to be an external memory device allowing only unencrypted Ember bootloader (EBL) files. Silicon Labs then added support for encrypted EBLs via a secure bootloader variant. For devices containing at least 512 kB of internal flash, Silicon Labs added the unencrypted local storage and secure local storage types, eliminating the need for an external storage device.

Note: Legacy secure bootloaders and local storage bootloaders are not supported on the EFR32MG family, but these configurations are supported with the Gecko Bootloader.

The legacy Ember application bootloaders also differ in how the recovery mechanism is presented. For most Ember application bootloaders, recovery mode involves a simple XModem serial transfer protocol. However, chips with USB capability can run an Ember application bootloader where recovery mode causes the chip to appear as a mass storage device to PCs. Mass Storage Device (MSD) Ember application bootloaders are available in both external storage and local storage variants. The recovery modes described in this document do not apply to Gecko Bootloader-based application bootloaders.

1.3 Acquiring a New Image

Application bootloaders rely on application code or the recovery mode to obtain new update images. The bootloader itself only knows how to read the update image stored in the download space and copy the relevant portions to the main flash block. This approach means that the application developer is free to acquire the new image in any way that makes sense for them (serial, OTA, etc.).

Typically application developers choose to acquire the new update image over-the-air (OTA) since this is readily available on all devices. For OTA bootloading in Zigbee® networks, Silicon Labs recommends using the standard OTA Upgrade cluster defined in the Zigbee Cluster Library (ZCL). Code for this cluster is available in the Zigbee Application Framework as several different plugins. AN728: *Zigbee Over-the-Air Bootload Cluster Server and Client Setup* walks through how this can be set up and run. This document can be used as a reference point for implementing application bootloading with different hardware. For OTA bootloading in non-Zigbee networks where a ZCL-based application layer is not available, the application layer may define its own means of conveying firmware data over the networking protocol, or the application developer may define a means of accomplishing an OTA image transfer between a source device and a target.

For customers who want to design their own application to acquire an image rather than using our application framework plugins, we provide some routines for interfacing with the download space. These routines allow you to get information about the storage device and interact with it. You can find the code and documentation for these routines in the source files `bootloader-interface-app.c` and `bootloader-interface-app.h`. If you do want to call these routines directly, it may be helpful to look at how the **OTA Cluster Platform Bootloader** plugin code works to ensure that these routines are used correctly. (See related files in the `app/framework/plugin/ota-bootload` directory of the EmberZNet installation for more information.)

1.4 Recovery Mode

Recovery mode is used as a failsafe mechanism to recover a module that has no valid application image. It is invoked by the Ember application bootloader when both the application image in the main flash block and the EBL update image in the download space are invalid. It can also be entered manually. Recovery mode uses a serial connection to download a new EBL file into the download space.

1.4.1 Manually Entering Recovery Mode

Recovery mode can be manually entered in two ways. The first method uses the FIB Monitor Mode, which is only available on EM3x-based devices. To perform this method, first start the EM3x device in FIB Monitor mode by grounding GPIO pin PA5 (nBOOTMODE) while resetting the chip. Then send a carriage return at 115200 baud over the UART serial port (SC1). This causes the FIB Monitor code to pass control to the bootloader installed in the main flash block and ensures that the bootloader is started in its recovery mode rather than allowing the application to boot normally.

The second method requires you to rebuild your application bootloader from the provided IAR Embedded Workbench project file, but it allows you to choose any GPIO or specify your own scheme for determining when to enter the recovery mode. To use this, you must modify the `bootloadForceActivation()` routine in `bootloader-gpio.c` (found in the `hal/micro/cortexm3/{mcuFamily}/bootloader` subdirectory of your stack installation) and rebuild the bootloader. An example utilizing PC6 is provided in `bootloader-gpio.c` and can be enabled by building the bootloader with `USE_BUTTON_RECOVERY` defined.

1.4.2 XModem Recovery Mode

Recovery mode uses the XModem protocol with CRC to upload a new image over the serial line. Once activated it immediately starts the upload sequence by sending 'C' characters out the serial line. The SC1 serial controller is used as a UART at 115200 baud, 8 bits, no parity, 1 stop bit. The 'C' characters are sent every 1 second until an XModem upload sequence is detected.

Note: To modify the UART settings used by the XModem Recovery Mode or move the serial functions to a different serial controller (if supported by the SoC), edit the `bootloader-uart.c` file found in the `hal/micro/cortexm3/{mcuFamily}/bootloader` subdirectory of the stack installation.

Use a terminal emulator on a PC to send the application EBL file to the node connected by serial cable.

Once the image has been saved to the download space, recovery mode resets the module and attempts to bootload the image just stored there.

1.4.3 Mass Storage Device (MSD) Recovery Mode

The MSD application bootloader available for EM358x and EM359x chips with USB replaces the aforementioned recovery mode with an MSD recovery mode. When the device enters MSD recovery mode, the download space is formatted as a blank FAT12 volume that enumerates as a USB mass storage device. The size of the volume is dictated by the size of the storage device (external or local). Any stored data is erased during the initialization of recovery mode. An EBL image file may be uploaded to the device by copying the file to the empty drive. To trigger a reset/bootload, disconnect USB and the module will attempt to locate and bootload the transferred image. The MSD recovery mode is currently only available for the unencrypted Ember application bootloader.

1.5 Errors during Ember Application Bootloading

1.5.1 Application Bootloader Errors

The application and the bootloader have limited indirect contact. Their only interaction is through passing non-volatile data across module reboots.

Once the application decides to install a new image saved in the download space it calls `halAppBootloaderInstallNewImage()`. This call sets the bootload mode and reboots the module. If the bootloader fails to install the new image, it sets the reset cause to `RESET_BOOTLOADER_BADIMAGE` and resets the module. Upon startup, the application should read the reset cause with `halGetExtendedResetInfo()`. If the reset cause is set to `RESET_BOOTLOADER_BADIMAGE`, the application knows the install process failed and can attempt to obtain a new image. A printable error string can be acquired from calling `halGetExtendedResetString()`. Under normal circumstances, the application bootloader does not print anything on the serial line.

1.5.2 Recovery Mode Errors

If recovery mode encounters an error while uploading an image, the chip will cancel the upload and reset. In XModem recovery mode, it also prints "Err" or "Stat" on the serial line followed by the error or status number in hex. After reset, recovery mode may be entered again if no valid images can be found or `bootloadForceActivation()` returns `true`. The following table lists some possible recovery mode bootload errors.

Table 1.1. Bootload Errors

Error/Status	Description
16	Timeout: Exceeded 60 seconds serial download timeout
18	File abort: Control-C on console
83	Write check error: Data read from external storage does not match data written
84	Image Size error: Download image size is greater than external storage space available

1.6 Example Application Bootload

For details on how to set up and run an application bootload using EM35x development kits, see *AN728: Over-the-Air Bootload Server and Client Setup*.

2. External Storage Ember Application Bootloader

2.1 Memory Map

The application bootloaders use the same memory map as the standalone bootloaders, but with an external storage device that is addressed separately. A diagram of the memory layout is shown in the following figure.

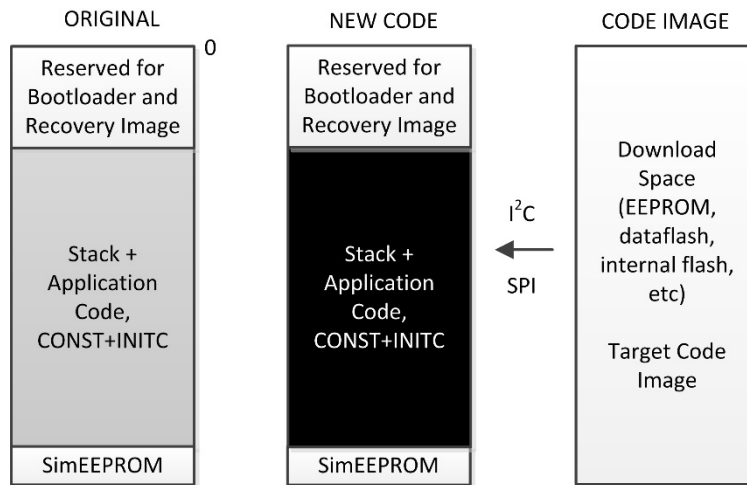

Figure 2.1. Application Bootloading Code Space (Typical)

2.2 Remote Memory Connection

Application bootloaders typically use a remote device to store the downloaded update image. This device can be accessed over either an I2C or SPI serial interface. Refer to [5. Appendix: Supported Serial Dataflash/EEPROM External Memory Parts](#) for a list of supported Dataflash/EEPROM devices. It is important to select a device whose size is at least the size of your flash in order to fit the application being bootloaded.

The default recommendation for external SPI serial flash is the MX25R, as this is available in standard and smaller packages, is supported by standard drivers, and has very low software-enabled sleep current without the need for an external shutdown control circuit. In general, customers should use parts that have low sleep current, don't require external shutdown control circuitry, and have software shutdown control. When using components with high idle/sleep current and no software shutdown control, an external shutdown control circuit is recommended to reduce sleep current.

Note that some of these chips have compatible pinouts with others, but there are several incompatible variations. A schematic for connecting the Atmel AT45DB021D SPI-based dataflash chip to an EM35x can be found in the document TS6, the *EM35x Breakout Board Technical Specification*. Contact Silicon Labs for details on connecting I2C or other SPI dataflash chips to an EM3x.

Read-Modify-Write pertains to a feature of certain dataflash chips that their corresponding driver exposes, and that is exploited by the bootloader library. Chips without this feature require a page erase to be performed before writing to that page, which precludes random-access writes by an application. When using the Zigbee Application Framework, the **OTA Simple Storage EEPROM Driver** plugin needs to be configured to take this into consideration.

Application bootloader images are supplied in S-record format (*.s37) for both I2C and SPI versions of the drivers noted in the table. In addition to these prebuilt images, you can build the bootloader image yourself using the supplied IAR Embedded Workbench project file found under `tool/bootloader-{part number}/{bootloader variant}/{bootloader variant}.eww`, such as `tool/bootloader-efr32mg1p132f256gm48/app-bootloader-spiflash/app-bootloader-spiflash.eww`, which uses the `spiflash-class1.c` driver by default. By modifying the project file and rebuilding the bootloader, you can do things like use a custom remote storage driver or set up your own default GPIO configuration.

Users may want to rebuild the bootloader image to turn on Serial Flash Hardware Shutdown Control, for instance. If your hardware implements this power-saving feature, then the `EEPROM_USES_SHUTDOWN_CONTROL` define symbol must be added or uncommented in the Board Header file when building the application bootloader, regardless of which dataflash chip is being used. Also note that, because the power-on state of these dataflash chips is "standby," an application that always wants to minimize its current draw should initialize and then immediately shutdown the dataflash as part of its bootup procedure.

On EM3x devices with multiple available serial controllers, the serial controller for the external memory device may be selected using the `EXTERNAL_FLASH_SERIAL_CONTROLLER` define symbol. If undefined, the driver may default to SC2 unless `SPI_FLASH_SC1` is defined. Furthermore, the serial rate may be defined with the `EXTERNAL_FLASH_RATE_LINEAR` (LIN) and `EXTERNAL_FLASH_RATE_EXPONENTIAL` (EXP) define symbols according to the following equation:

$$rate = \frac{PCLK}{(LIN + 1) * 2^{EXP}}$$

Where PCLK is the SYSCLK divided by two (generally 12 or 6 MHz). If left unspecified, the I2C driver will default to 400 kbps in master mode, and the SPI driver will default to 12 MHz, master mode, MSB transmitted first, sample on leading edge, rising leading edge.

3. Local Storage Ember Application Bootloader

A local storage bootloader is essentially an application bootloader with a data flash driver that uses a portion of the on-chip flash for image storage instead of an external storage chip. This simplifies design, but also means that less storage space is available for the application and the SimEEPROM needed for application token storage during operation. Since a new image has to fit in this storage region it needs to be roughly half of the chip's flash, which means that this type of bootloader is only feasible on chips with enough flash like some EM358x and EM359x variants.

3.1 Memory Map

Since the storage region for the local storage application bootloader is in the internal flash memory map, this bootloader type shrinks the application area and adjusts the location of the SimEEPROM. A diagram of this memory layout is shown in the following figure.

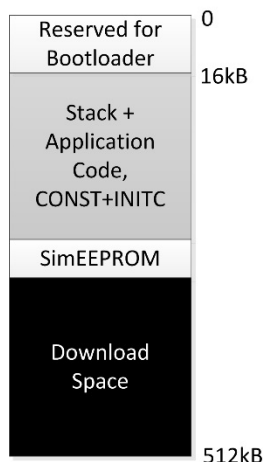

Figure 3.1. Local Storage Bootloader Memory Map

The numbers in the above diagram assume the standard 8 kB SimEEPROM. If you select a larger SimEEPROM size, there are some changes in the size of the download space since the maximum size for your application is decreased. (See *AN703: Using the Simulated EEPROM for the EM35x and Mighty Gecko Family SoC Platforms* for further information about SimEEPROM and the memory requirements of different SimEEPROM models.) The download space size is chosen automatically to be half of the memory available to your application with some additional space added for EBL format overhead. Specifically, we use the following formula with overhead set equal to 2 kB.

```
DownloadSpace_size = (Flash_size - SimEEPROM_size - 16kB)/2 + Overhead
```

If you require more fine-grained control over the size of the download region, please contact Silicon Labs support for more information.

3.2 Building your Application

Since the local storage application bootloader changes the chip's flash memory layout you must build your application with knowledge of this. To accomplish this, you must add the `LOCAL_STORAGE_BTL` global define to your IAR project file. If you're creating your project file through AppBuilder in Simplicity Studio, then this will be done for you as long as you select Local Storage Bootloader from the bootloader dropdown.

If you do not do this, your application will be built with a storage region size of 0 bytes by default. An image built like this will not be deemed valid by the local storage application bootloader because it would result in a dangerous situation where your device could never be updated again.

4. Secure Ember Application Bootloaders

Most Ember application bootloaders can have secure variants designed to only accept encrypted EBL files. Encrypted EBL files are secured using a symmetric key that is stored among the device's manufacturing tokens in an area of the chip that can be secured (via read protection) and kept secret. This allows the device to verify that the image comes from someone who knows the key and not just any- one who knows how to create an EBL file. This also ensures that the image cannot be read by anyone who does not have the symmetric key.

Note: Secure bootloader support and local storage bootloader support for the EFR32MG family of parts are available through the Gecko Bootloader only.

4.1 Security Considerations

The secure bootloader uses the encrypted EBL file format to protect the data both in transit and while stored on the device. This format uses AES-128 operating in CCM* mode to encrypt the contents of the file. For more information about this file format, see section 3.2 of document *UG103.6: Bootloading Fundamentals*.

Since the format uses symmetric key encryption, the key must be stored on both the device and the machine used to generate encrypted EBLs. The keys must be created and loaded on the device in order for the secure bootloader to work. Developers may choose to have one key per device, one key for all devices, or any other partitioning. If you choose to have different keys for some devices, you must generate different encrypted EBL files for these devices and ensure that the correct EBL is sent to the correct device. Whatever you do, the key files must be kept safe on the machine generating the encrypted EBLs. Once a key file is released an attacker can encrypt and sign images for any device that uses that key file.

The key must also be kept safe on the devices in the field. The security key for the device is stored in the protected manufacturing token area (CIB region for EM3x-based devices and Lockbits region for EFR32-based devices) at a known location. To prevent an attacker from accessing this, Silicon Labs recommends turning on the Flash Readout Protection feature of the chip. This will prevent a debugger from being able to connect to the chip and read out the protected manufacturing token data. It's also important to make sure that your application is robust against software attacks that could attempt to read out this key. Keep in mind that once this protection is enabled there is no easy way to modify the manufacturing token to change the security key without erasing the entire device.

4.2 Using Simplicity Commander

Simplicity Commander is a single, all-purpose tool to be used in a production environment. It is invoked using a simple Command-Line Interface (CLI) that is also scriptable. You can use Simplicity Commander to perform these essential tasks:

- Creating encrypted EBL images
- Generating a keyfile
- Encrypting an EBL image
- Decrypting an EBL file

For more information on executing the commands to complete these tasks, refer to *UG162: Simplicity Commander Reference Guide*.

5. Appendix: Supported Serial Dataflash/EEPROM External Memory Parts

Note: The low power devices are recommended for battery-operated applications. Use of the other listed devices will decrease battery life due to higher quiescent current, but this can be mitigated with external shutdown FET circuitry if desired.

Table 5.1. Serial Dataflash/EEPROM External Memory Parts Supported on the EM3x

Manufacturer Part Number	Interface	Size	Quiescent Current (μ A)*	Read-Modify-Write? **	Pin-compatible with	Driver
